Performance Analysis: Slow Database Query (Node.js / PostgreSQL)

Error Description / Issue:

The application experiences slow performance when retrieving customer orders. In particular:

- Query execution takes about **8–10 seconds** for customers who have many orders.
- The main cause is retrieving data from several related tables (such as **orders, order_items, and products**) without proper indexing.
- This leads to **application timeouts** and negatively affects the **user experience**.

Root Cause:

1. **Missing Indexes:**
   Only primary keys are indexed. When large tables—such as **order_items** with around 500,000 rows—are joined without additional indexes, the database performs full table scans, which are slow.
2. **Inefficient Joins:**
   The query joins multiple tables (orders → order_items → products → customers) without filtering data beforehand, increasing processing time.
3. **Retrieving Too Much Data:**
   The query returns all columns instead of only the necessary ones, which increases memory usage and slows down network transfer.
4. **No Pagination or Limits:**
   For customers with many orders, retrieving all records at once increases execution time significantly.

Key Pattern:
Joining large tables without proper indexing leads to slow database performance.

Suggested Solutions / Optimizations:

1. **Create Indexes for Filtering and Joins:**
   Add indexes to columns frequently used in **WHERE** clauses and **JOIN** operations to speed up searches.
2. **Reduce the Number of Columns Retrieved:**
   Instead of using **SELECT ***, only request the specific fields needed. This reduces memory usage and improves response time.

3. **Use Pagination or Batch Processing:**
   Retrieve records in smaller groups rather than loading everything at once. Techniques such as **LIMIT** and **OFFSET** can help manage large datasets.
4. **Review the Query Execution Plan:**
   Use PostgreSQL tools such as **EXPLAIN ANALYZE** to identify slow operations like sequential scans or inefficient joins.
5. **Advanced Optimization (Optional):**
   - Use **materialized views** or summary tables for frequently requested data.
   - Implement **connection pooling** in Node.js to improve overall query performance.

Learning Points / Key Concepts:

1. **Indexing:**
   Proper indexing significantly improves search and join performance in large datasets.
2. **Selective Data Retrieval:**
   Requesting only required columns reduces memory usage and network load.
3. **Pagination:**
   Dividing large datasets into smaller sections helps prevent timeouts and reduces server strain.
4. **Query Planning:**
   Understanding database query plans helps identify performance bottlenecks.
5. **Database vs Application Optimization:**
   Improving database structure can often be more effective than modifying application code.

Reflection Questions:

1. How did the optimization change your understanding of performance?
I learned that system performance depends not only on code efficiency but also on how data is stored and retrieved. Poor indexing can make queries much slower, even if the code itself is correct.

2. What performance improvements were achieved?
Adding indexes and reducing unnecessary data retrieval can lower query time from around **10 seconds to less than 1 second**, which greatly improves user experience.

3. What new insights did you gain about bottlenecks?
I discovered that missing indexes on foreign keys and frequently filtered columns are common causes of slow database queries. Large sequential scans can significantly reduce performance.

4. How would you handle similar issues in the future?
I would start by analyzing the query plan using **EXPLAIN ANALYZE**, then add indexes where needed, limit returned data, and implement pagination for large datasets.

5. What tools would you use to detect performance issues early?

- PostgreSQL tools such as **EXPLAIN**, **EXPLAIN ANALYZE**, and **pg_stat_statements**
- Node.js profiling tools such as **node --inspect**
- Running tests on large datasets to simulate real-world usage
